**ABSTRACT**

Stormwater management is a vital component on roadway construction and site development projects. Stormwater detention ponds are often utilized to protect neighborhoods against flooding and streams from environmental degradation. Detention systems are located underground where land is expensive or where there are other concerns such as safety or mosquitoes. Pipes, pipe arches and concrete vaults are typically installed in underground systems. Geosynthetic materials are utilized in a new underground stormwater detention system which offers advantages over traditional systems. Essentially, a geotextile or geomembrane liner system is installed within an excavation. Around the perimeter of the excavation, walls are constructed with geosynthetic reinforcement and open graded stone creating a large underground chamber. Inlet and outlet pipes extend through the perimeter liner system and wall face into the chamber. A reinforced concrete roof is installed above the open chamber and supported by the perimeter abutments/walls. Finally, the liner system is installed over the stone surface before the cover soil brings the site to grade. A large open chamber is constructed with reinforced stone having a high porosity that contributes to the storage capacity. This geosynthetic based underground detention system (GDS) has among other attributes the advantage of low cost, well established AASHTO design standards, small footprint and ease of inspection and maintenance.

## **INTRODUCTION**

Detention systems release stormwater through an outlet at a controlled rate. Retention, or recharge, systems percolate the stormwater into the water table. Flood control is the primary design objective for both systems while stream bank erosion protection is an additional consideration. The standard of practice is to insure that the post-development flow from a site does not exceed the pre-development flow for a given storm event. From a practical standpoint, many urban and suburban neighborhoods were developed along water bodies and expanded outward. The streams, creeks and gullies that pass through these neighborhoods see greater flows as development expands upstream. The most fundamental role of stormwater management is to protect these vulnerable communities from flooding.

Another key concern is the quality of the stormwater flowing into receiving water bodies. The Environmental Protection Agency (EPA) has enacted the National Pollution Discharge Elimination Stormwater (NPDES) Program to regulate the discharge of stormwater. Many states are in the process of enacting legislation to protect local waterways from stormwater pollution. At a minimum these regulations will limit the turbidity of stormwater discharge on construction sites to 280 NTU's by 2014 (2011 for sites greater than 20 acres).

## **TRADITIONAL UNDERGROUND DETENTION SYSTEMS**

Concrete vaults have a long history in stormwater detention. These modified box culverts are simple, structurally sound and easy to inspect and maintain. They can be precast or formed and poured on site. Concrete vaults are the most expensive underground stormwater detention system.

High density polyethylene (HDPE) pipes dominate the small diameter pipe market but are not manufactured above 60 inch (152.4 cm) diameters.

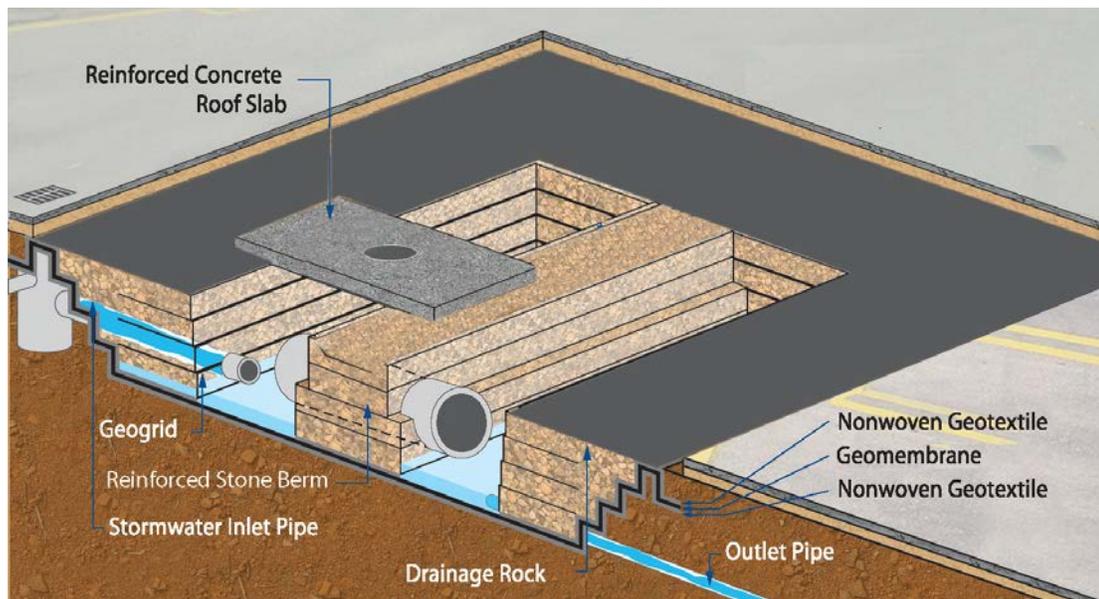

Corrugated steel pipe (CSP) is manufactured up to 144 inch (365.8 cm) diameters. Pipe volumes increase exponentially with diameter so it is economical to design with large diameter pipes giving some consideration to permitting issues for oversized freight.

CSP and HDPE pipes are flexible pipes that transfer stresses to the surrounding soil. Design standards are based on structural backfill properties and compaction efforts. As a result, State Department of Transportation (DOT) specifications set specific gradation and compaction requirements for flexible pipes. In most instances imported structural backfill is required which increases overall project costs.

Half round plastic pipe arches are fairly new to the stormwater detention market. By eliminating the need to backfill below the haunches of round pipe these pipe arches can be more tightly spaced. Also, the open bottom eliminates the flow restrictions and accelerated degradation associated with perforations in round pipes on retention applications. These pipe arch systems are designed with an open graded stone backfill. The 40% stone porosity increases the system's storage capacity and makes plastic pipe arches cost effective at low profiles.

## **GEOSYNTHETIC BASED UNDERGROUND STORMWATER DETENTION/RETENTION SYSTEM (GDS)**

1  
2 In traditional detention systems the storage chamber is a manufactured product  
3 designed to withstand sidewall and overburden pressures. The nature of the GDS system is  
4 to create a storage chamber with stabilized stone sidewalls capable of supporting a roof.  
5 Given the application, water forces are an important design consideration. If water drains  
6 from the chamber faster than it drains from the backfill, the perimeter walls will experience a  
7 rapid draw down condition. The use of angular, open graded,  $\frac{3}{4}$  - 1  $\frac{1}{2}$  inch (19-38 mm),  
8 washed stone eliminates pore pressures and has the added benefit of increasing storage  
9 capacity with a 40% void ratio. It is the combination of the large chamber and the porosity  
10 of the stone utilized to construct the chamber that makes a GDS system cost effective.

15

## 16 DESIGN STANDARDS

17  
18 Innovation in the civil engineering market, particularly the transportation segment,  
19 can be challenging. The scrutiny applied to new technologies reflects the replacement costs  
20 and safety issues that might result from a failure. While still innovative, the GDS system is  
21 comprised of components with well established design and performance histories.  
22

## 23 LINER SYSTEM

24  
25 The GDS starts with a liner system, critical to keep the surrounding native soil from  
26 piping into the perimeter stone. In detention applications, a geomembrane is installed with  
27 appropriate geotextile layers for protection against the angular stone. In retention  
28 applications, a geotextile is installed to allow for percolation. In the past, detention systems  
29 were the standard of practice. In recent years many stormwater practitioners have focused on  
30 maintaining the pre-development water balance by recharging the water table. However, the  
31 percolation rate of the native soil and in certain regions the presence of karst limits the use of

1 recharge systems. More importantly, long term clogging issues present the biggest challenge  
2 to underground stormwater recharge systems.  
3  
4

5  
6  
7 **GDS liner system**

8  
9 **PERIMETER WALLS**

10  
11 The perimeter walls are designed as mechanically stabilized earth (MSE) structures  
12 based on the design procedures outlined in AASHTO (1999a). In order to maintain optimum  
13 flow a wrap facing is utilized at the wall face. While MSE structures have been used for  
14 years along river channels and more recently to stabilize the walls around surface detention  
15 ponds, it was considered prudent not to underestimate water forces. Geogrid reinforcement  
16 was selected to positively confine the stone aggregate and optimize flow. Another early  
17 design decision proved to be fortuitous. The geogrids were spaced at 9 inch (22.8 mm) lifts  
18 to further confine the stone and to insure compaction in each lift.

5 **GEOSYNTHETIC-REINFORCED SOIL TECHNOLOGY**  
6

7 The number of bridges in the United States requiring repair or replacement is  
8 daunting. The Federal Highway Administration (FHWA) has developed the Bridge of the  
9 Future Program to address this issue. One of the program's initiatives is the Geosynthetic-  
10 reinforced soil (GRS) integrated bridge system (1). The goal of this bridge system is to  
11 simplify the design and reduce the cost of simple single span bridges 70-90 feet (21-27m)  
12 long. GRS design methodology is based on the performance of several full-scale  
13 experiments and production abutments as well as an increasing list of real world applications.  
14 This methodology is distinctly different from well established MSE design standards. The  
15 differences can most readily be seen in the reinforcement material's properties and spacing.  
16 GRS structures are characterized by tightly spaced geosynthetic layers with much less  
17 consideration paid to the long term strength of the reinforcement. By definition the 9 inch  
18 (22.8 mm) spacing selected for the GDS walls allows them to be classified as GRS structures  
19 which also meet MSE design standards.

20 While the GRS classification helps quantify an extra degree of conservatism in the  
21 design, the big benefit is much more practical. Close inspection of the FHWA GRS  
22 integrated bridge cross section reveals that the bridge superstructure rests directly on the  
23 GRS abutment wall. The GRS bridge abutment design does not include a bearing pad.  
24  
25

## BEARING SILLS

The original GDS system design had a concrete bearing curb. However, it was apparent that the self weight of the roof and the overburden soils locked the deck in place. The bearing curb, while a standard feature to structural engineers, might be considered extraneous to geotechnical engineers.

GRS bridge abutment test results demonstrated that the concrete bearing curb was not necessary. Bearing sills on the GRS structures were loaded to 13 Tons/SF (1,244 kPa), the maximum load of the equipment, without failure. Small cracks were observed in the concrete wall facing at 4 Tons/SF (382.8 kPa) which sets a serviceability limit for design purposes (2). The field performance of the bridge abutments supports the test data.

Another beneficial feature of the GRS bridge design was the pavement performance at the interface of the roadway and the bridge abutment. The typical “bump” at the approach interface is almost undetectable with equally impressive performance in the areas of cracking and settlement.

Recognizing that relative lengths of bridge spans are very long and that the decks are at grade, the placement of the roof deck directly on the perimeter walls of a GDS underground stormwater system is a natural application for the GRS technology.

The typical sill area for the concrete deck atop the detention system perimeter walls is limited to 2 Tons/SF. Immediately below the bearing sill the stone size is reduced and additional reinforcement layers are included. A geotextile wrap is added to the wall face in this area to prevent raveling of the smaller stones. Upon placement of the concrete roof and cover soil it has been observed that there is no movement whatsoever in the area of the bearing sill.

**GDS bearing sill**

## ROOF DECK

The roof deck for the GDS system is designed to AASHTO bridge standards (Section 3.24.12, “Distribution of loads and design of concrete slabs”). The roof deck can be installed flush with the surface but this requires the roof to match a sloping surface precisely. Pipe plumbing and aesthetic issues generally favor burying the roof. The roof deck can be cast in place but precast panels simplify and speed construction. The precast panels are sized to optimize freight and enable an excavator to pick and place the slabs on site. The elevation of

1 the roof deck is typically set such that the minimum clearance allows for a road base and  
2 asphalt overlay. The bottom elevation of the deck must also be checked to make sure it does  
3 not rise above the lowest upstream manhole cover/grate. Manhole access is provided in the  
4 roof deck to enable inspection and maintenance of the chamber.  
5

6  
7  
8  
9

### **GDS roof deck installation**

## **System Features**

11

12 The storage volume of the chamber combined with the porosity of the stone utilized  
13 to construct the chamber allow for a much smaller GDS footprint than pipes or pipe arches.

14 Much like pipes, GDS systems become more efficient with depth. As mentioned  
15 earlier, pipe volumes increase exponentially with diameter while costs rise at a linear rate  
16 making large diameter pipes more efficient. Given that the roof is the most expensive  
17 component of the GDS system, unit costs also decrease with depth.

18 A single chamber GDS system can be extended to store any stormwater volume.  
19 However, site constraints might limit the length of a GDS system. In these instances interior  
20 piers, or two sided walls, may be constructed within the chamber to increase the chamber  
21 width.

22

## **DETENTION APPLICATIONS**

23  
24

1           In detention applications the most cost effective solution involves locating the roof of  
2 the detention system as high as the surface grades and upstream manholes permit while  
3 lowering the floor as low as the outfall elevation will allow. An overflow device is needed to  
4 protect against upstream flooding on storms that exceed the maximum design storm event.  
5 Typically overflow is provided in a manhole immediately downstream of the detention  
6 system. Within the manhole, a weir is installed between the inlet and outlet pipes with a top  
7 elevation set at the high water elevation in the detention system. Orifices within the weir are  
8 sized and located to insure that smaller design storm event outflows do not exceed  
9 preconstruction rates.

## 11   **RETENTION APPLICATIONS**

13           Retention applications allow for deep systems with consideration for soil permeability  
14 and the elevation of the water table. Retention systems require an overflow device similar to  
15 the detention system weir described above. However, the major concern in  
16 recharge/retention systems is clogging of the geotextile floor.

17           Traditional leach pads are comprised of a stone layer above a geotextile filter. This  
18 cross section creates a “gap graded” condition. In addition, stormwater flow carries a  
19 sediment load, much of it suspended, on a regular basis into the leach pad. Lastly, the planar  
20 geotextile concentrates sediment on a “sheet”. Each one of these issues is a red flag for  
21 clogging. While Best Management Practices (BMP’s) upstream of the leach pad can limit  
22 the sediment load and the percentage of suspended solids, the accumulation of a critical  
23 clogging load is a function of time. In these circumstances, engineers need to consider two  
24 factors; risk and accessibility. The overflow weir protects the upstream development from  
25 flooding. However, the geotextile is inaccessible. The repair cost for clogging is the  
26 replacement cost for the entire system. The movement from detention systems to  
27 recharge/retention systems will largely depend on the ability to address the issue of clogging.

## 29   **ECONOMICS**

31           Site conditions, local regulations and regional commodity prices influence the relative  
32 cost of all detention systems. However, some generalizations regarding the cost  
33 effectiveness of the GDS system can be made. The concrete roof and stone comprise the  
34 major material cost items. Given the stone porosity’s contribution to storage capacity, the  
35 concrete roof cost becomes even more significant. At depths of 6-8 feet (1.83-2.44 m) GDS  
36 material costs are roughly 60 percent of pipe and pipe arch systems, before accounting for  
37 excavation and installation costs. As the available profile on a project increases the relative  
38 cost advantage of the GDS system improves.

39           On tight sites, on sites where off site hauling is required, on sites where rock is  
40 present or where stormwater treatment is required, GDS systems can offer additional savings.

## **INSPECTION AND MAINTENANCE**

Detention systems collect sediment. Backhoes can remove sediment from above ground ponds. With the exception of concrete vaults and large diameter pipes, most underground detention systems are inaccessible. Maintenance involves backwashing and localized removal from outside the system. The large open GDS chamber allows for easy inspection and maintenance. In retention applications, it is the only system that enables the inspection and, where needed, replacement of a clogged geotextile. As the stormwater quality regulations evolve the ability to inspect and maintain detention systems will increase in importance.

## **STORMWATER QUALITY**

Sand filters are a time proven pollutant remover. However, in underground applications the cost of the concrete vault required to house the sand filter is expensive. As a result, many new technologies are entering the marketplace to meet regulatory pollutant removal requirements. These technologies include vortex chambers and filter cartridge systems housed in smaller concrete vaults.

The GDS system enables the construction of a traditional sand filter by lining the chamber walls. Interior piers may be constructed within the chamber to provide the required sand surface area. The performance of the system mimics that of a concrete vault sand filter but at a much lower cost.

1  
2 **GDS stormwater treatment and detention system.**

3  
4 **GREEN SOLUTION**

5  
6 Stormwater volumes are typically stored in a product, like pipe, manufactured in a plant and  
7 shipped to a jobsite. This traditional solution entails shipping the entire storage volume on a  
8 series of trucks. Flexible pipe, the most common detention system, also requires a structural  
9 backfill imported from the local quarry. The GDS storage chamber is constructed on site  
10 with geosynthetics which can easily fit on a single truck. The porosity and weight of the  
11 stone used to form the chamber results in far fewer truck loops from the local quarry. The  
12 precast roof panels can be manufactured locally and will require a fraction of the trucks  
13 needed to ship pipe. Combined with a reduced excavation these advantages make GDS a  
14 “green” solution where underground stormwater detention is required.

15  
16 **CONCLUSION**

17  
18 GDS systems offer a cost effective alternative to traditional underground stormwater  
19 detention and retention systems. A smaller footprint will provide engineers with more design  
20 flexibility. As stormwater quality regulations are enacted those responsible for compliance  
21 will appreciate the accessibility of the large open GDS chamber. No other retention system  
22 enables the inspection and replacement of clogged geotextiles. Lastly, the chamber enables  
23 the construction of an efficient underground sand filter where regulations require stormwater  
24 treatment.

25 The liner, reinforced walls and concrete deck comprising GDS systems are designed  
26 to AASHTO standards. While the system is novel the components have been thoroughly  
27 vetted by the engineering community.

28 The nation’s infrastructure needs are great and stormwater management requires a  
29 growing percentage of construction budgets. GDS systems offer engineers an innovative tool  
30 to accomplish more with less.
